

# A differential evolution-based approach for fitting a nonlinear biophysical model to fMRI BOLD data

Pablo Mesejo, Sandrine Saillet, Olivier David, Christian Bénar, Jan M. Warnking and Florence Forbes

**Abstract**—Physiological and biophysical models have been proposed to link neuronal activity to the Blood Oxygen Level-Dependent (BOLD) signal in functional MRI (fMRI). Those models rely on a set of parameter values that cannot always be extracted from the literature. In some applications, interesting insight into the brain physiology or physiopathology can be gained from an estimation of the model parameters from measured BOLD signals. This estimation is challenging because there are more than 10 potentially interesting parameters involved in nonlinear equations and whose interactions may result in identifiability issues. However, the availability of statistical prior knowledge about these parameters can greatly simplify the estimation task. In this work we focus on the extended Balloon model and propose the estimation of 15 parameters using two stochastic approaches: an Evolutionary Computation global search method called Differential Evolution (DE) and a Markov Chain Monte Carlo version of DE. To combine both the ability to escape local optima and to incorporate prior knowledge, we derive the target function from Bayesian modeling. The general behavior of these algorithms is analyzed and compared with the *de facto* standard Expectation Maximization Gauss-Newton (EM/GN) approach, providing very promising results on challenging real and synthetic fMRI data sets involving rats with epileptic activity. These stochastic optimizers provided a better performance than EM/GN in terms of distance to the ground truth in 4 out of 6 synthetic data sets and a better signal fitting in 12 out of 12 real data sets. Non-parametric statistical tests showed the existence of statistically significant differences between the real data results obtained by DE and EM/GN. Finally, the estimates obtained from DE for these parameters seem both more realistic and more stable or at least as stable across sessions as the estimates from EM/GN.

**Index Terms**—functional MRI, Biophysical Parameters Estimation, Differential Evolution, Stochastic Optimization.

## I. INTRODUCTION

Functional magnetic resonance imaging (fMRI) is a neuroimaging modality to study brain function. The most common fMRI signal is the Blood-Oxygen-Level-Dependent (BOLD) signal, related to local changes in the concentration of deoxyhemoglobin. The relationship between the BOLD signal and neuronal activity is indirect: an increase in synaptic activity triggers focal vasodilation, leading to local functional

hyperemia (the local increase of blood flow to the brain tissue). This strong increase in blood flow exceeds the relative increase in oxygen consumption, leading to an overall increase in blood oxygenation and, thus, an increase in the MRI signal.

Usually, BOLD fMRI data are analyzed by comparing the measured dynamic signal in each voxel to a linear model of predicted responses obtained by convolving the known experimental design (“paradigm”) with an assumed hemodynamic response function. However, the dynamics underlying neural activity and hemodynamic physiology are believed to be nonlinear and there is an increasing interest in using physiologically plausible models in fMRI analysis. In the past fifteen years, physiological models have been proposed to describe the processes that link neuronal and hemodynamic activities in the brain. Different variations of the widely used “*Balloon model*” [1] have been introduced to provide a high-level description of the physiological processes underlying the hemodynamic response, from neuronal activation to the BOLD signal [2], [3]. These models depend on several physiological parameters for which different competing values have been proposed in the literature [3], [4]. Most approaches currently use one of these empirical sets of values [5], [6], [7], although it has been shown that the selection of these parameters had a more critical impact than the choice of the Balloon model variant itself [5], [7]. Identifying the model describing the neurovascular coupling is required if accurate inferences on the timing on the underlying neuronal signals are to be made, such as in dynamic causal modelling (DCM) [8]. The aim of the present work is to estimate the underlying physiological parameters from observed BOLD data in a single brain region to obtain relevant neuropathophysiological information on the animal or patient studied.

A general method for estimating parameters involved in a dynamic system has been proposed [9], based on a Bayesian inversion scheme which allows the incorporation of prior knowledge. Such *a priori* knowledge is typically summarized by a Gaussian distribution for each physiological parameter and provides a generally accepted consensus avoiding the commitment to arbitrarily fixed values. The method in [9] has then been widely used as the method of reference to estimate the hemodynamic response in DCM, and is implemented in the Statistical Parametric Mapping (SPM) software [10]. It is based on an Expectation-Maximization Gauss-Newton search (EM/GN) which requires a Laplace approximation to estimate the conditional expectation and covariance of the parameters. Alternative approaches include sampling, e.g. Monte Carlo Markov Chain (MCMC), or other stochastic techniques, e.g. Metaheuristics (MHs). Sampling techniques offer a number

of attractive features such as robust and reliable performance, and ability to escape local optima. MHs are in addition zero-order optimization algorithms that do not even require the availability of the objective function in analytic form.

MHs have successfully been used in biomedical data analysis problems [11], [12]. In particular, they have been employed to find optimal experimental designs for event-related fMRI experiments [13], [14], [15] and to investigate whether they can accelerate the model search in DCM [16]. In the DCM context, the need for the Laplace approximation can be relaxed by a MCMC implementation of the Bayesian inversion scheme and it can be shown that the Laplace approximation actually yields sensible inferences under a large set of conditions [17]. However, the work cited above focuses on DCM and neuronal parameter estimation while nothing is reported on the impact on the non-neuronal physiological parameters. Furthermore, MCMC usually needs thousands of iterations to converge, constraints are not easy to introduce (compared to MHs) and it does not provide mechanisms to control the trade-off exploration-exploitation<sup>1</sup>. This prevents estimating more than a few parameters in practice. A different approach considers the Balloon model in a non-Bayesian setting using standard MHs with an objective function, or so-called *fitness* function<sup>2</sup>, which does not include prior information [18]. Without such valuable prior knowledge, it is quite challenging to include all the parameters into the proposed optimization scheme due to potential identifiability issues. It results that this approach is limited to the estimation of 3 out of the 15 physiological parameters considered in this paper.

In this work, our goal is to combine both the benefits from a Bayesian approach which allows incorporation of prior knowledge and from general-purpose global optimization techniques able to effectively explore the search space. Traditionally, an EM/GN optimization procedure is run starting from the prior mean estimates for each parameter. However, in this paper we are concerned with the study of other alternatives to this approach, and we analyze the average behavior of two stochastic algorithms when solving this problem (so that a potential user can know what to expect when using each of the proposed methods). According to the Bayesian inversion scheme of [9], we derive a fitness function that is directly comparable to the one employed by the EM/GN search within the SPM software package. It follows an estimation procedure able to estimate all physiological parameters of interest while being less likely to get trapped in local optima. This novel method is assessed on challenging real and synthetic EEG/fMRI data sets obtained in rats exhibiting epileptic activity. A qualitative and quantitative comparison between two stochastic approaches and with the EM/GN approach shows the ability of stochastic methods, and in particular MH-based approaches, to provide physiologically plausible parameter values without the need of computing derivatives or estimating complex functionals. We believe the

idea of a principled Bayesian-driven MH method is new in this context and we used it to address the challenging issue of estimating 15 parameters which are traditionally manually set or, for only a few of them, determined by using conventional but potentially suboptimal local search methods like EM/GN. This could have a strong impact on a number of fMRI studies.

## II. THE EXTENDED BALLOON MODEL

The Balloon model was first proposed in [1] to link neuronal and vascular processes by considering the venous vascular compartment as a balloon that inflates passively under the effect of actively controlled upstream blood flow variations. More specifically, the model describes how, after some input to the neuronal population, local arteriolar blood flow  $f_{in}(t)$  increases and leads to the subsequent augmentation of the local deoxygenated blood volume  $v(t)$ . The incoming blood is strongly oxygenated and, since the relative blood flow increase exceeds the increase in oxygen consumption, local deoxyhemoglobin concentration  $q(t)$  decreases and induces a BOLD signal increase. This model was subsequently extended [3] to include the effect of neuronal activity on the variation of some auto-regulated flow inducing signal  $s(t)$  so as to eventually link neuronal to hemodynamic activity. Variable  $n_e(t)$  represents the activity of the excitatory neuron population and  $n_i(t)$  the inhibitory neuron population [19]. The experimentally controlled input function (stimulus) is represented by  $u(t)$ . In the following, the explicit time dependence ‘(t)’ of the state variables will be omitted for compactness. The global physiological model corresponds to a nonlinear system with six state variables  $\mathbf{x} = \{n_e, n_i, s, f_{in}, v, q\}$  related to the excitatory and inhibitory neuronal activity, normalized flow inducing signal, local blood flow, local deoxygenated blood volume, and deoxyhemoglobin concentration. Their interactions over time are described by the following nonlinear differential equations:

$$\begin{aligned} \frac{dn_e}{dt} &= -En_e - e \left( A + Bu^{se} + D^T \begin{pmatrix} n_e \\ s \\ f_{in} - 1 \end{pmatrix} \right) n_i + Cu^{se} \\ \frac{dn_i}{dt} &= n_e - 2En_i, \quad \frac{ds}{dt} = n_e - sd s - ar(f_{in} - 1), \end{aligned} \quad (1)$$

$$\frac{d \ln(f_{in})}{dt} = \frac{s}{f_{in}}, \quad \frac{d \ln(v)}{dt} = \frac{1}{tt} \frac{f_{in} - v^{\frac{1}{\alpha}}}{v},$$

$$\frac{d \ln(q)}{dt} = \frac{1}{tt} \left( \frac{1 - (1 - E_0)^{\frac{1}{f_{in}}}}{E_0} \frac{f_{in}}{q} - v^{\frac{1}{\alpha} - 1} \right)$$

From these state variables, the observed BOLD signal  $y$  is derived using an observation equation that includes intra- and extravascular BOLD signal components [2]:

$$y = V_0 \left[ k_1 (1 - q) + k_2 \left( 1 - \frac{q}{v} \right) + k_3 (1 - v) \right] \quad (2)$$

where  $k_1, k_2, k_3$  are physiology- and scanner-dependent constants  $k_1 = 4.3 \theta_0 E_0 TE$ ,  $k_2 = \varepsilon r_0 E_0 TE$  and  $k_3 = 1 - \varepsilon$ ,

<sup>1</sup>Diversification/exploration implies generating diverse solutions to explore the search space on a global scale, and intensification/exploitation implies focusing the search onto a local region where good solutions have been found.

<sup>2</sup>We use the term fitness function, rather than objective or cost function, because this is the term most commonly used within the evolutionary computation research. This fitness function traditionally needs to be minimized.

in their updated version with respect to the original formulation [7]. The value  $\theta_0$  is the frequency offset at the outer surface of the magnetized vessel for fully deoxygenated blood,  $40.3 \text{ Hz} \cdot b_0 / 1.5 \text{ T}$ , scaled linearly from the SPM default value of  $40.3 \text{ Hz}$  at  $1.5 \text{ T}$  to the magnetic field strength  $b_0$  the MRI data were acquired at. The echo time is represented by  $TE$  and  $r_0$  is the slope of the relation between the intra-vascular relaxation rate and oxygen saturation, which is set to  $300 \text{ Hz}$  for a magnetic field strength of  $4.7 \text{ T}$ , a hematocrit of  $0.4$  and a blood saturation of  $0.5$  [20].  $E_0$  is the oxygen extraction fraction at rest and is considered as a free parameter as well as  $\varepsilon$ , the ratio of intra- to extra-vascular BOLD signal. The remaining ones,  $A, B, C, D$  and  $E$ , are parameters as in nonlinear DCM [21],  $\mathbf{D} = (D_1, D_2, D_3)^T$  being the new component in the nonlinear state equation above. The parameter  $C$  is a scaling parameter that converts the EEG response amplitude to a neuronal stimulus. This scaling depends on the EEG electrode placement and has no easily accessible physical meaning. Parameter  $se$  is the spike exponent introduced for the present dataset to control the scaling of the synaptic activity with respect to the spike amplitude derived from local field potentials (LFPs),  $sd$  is the vasodilatory signal decay,  $ar$  is the rate constant for autoregulatory feedback by blood flow, and  $tt$  represents the transit time of blood from the arteriolar to the venous compartment. The Grubb's vessel stiffness exponent corresponds to  $\alpha$ , while  $V_0$  is the resting venous cerebral blood volume fraction. The whole model depends on 15 different scalar parameters to optimize  $\boldsymbol{\theta} = \{A, B, C, D, E, se, sd, ar, tt, \alpha, E_0, V_0, \varepsilon\}$ . All this information is summarized in Table I.

### III. BAYESIAN ESTIMATION OF DYNAMICAL SYSTEMS

MHs require the definition of a fitness function to measure the goodness of the parameters found. We use the Bayesian inversion scheme of [9] to derive an appropriate fitness function. In the Balloon model, the first part describes the transitional dynamics of the state variables  $\mathbf{x} = \{n_e, n_i, s, f_{in}, v, q\}$ . The system is defined as  $\frac{d\mathbf{x}}{dt} = f(\mathbf{x}, u, \boldsymbol{\psi})$ , with  $\boldsymbol{\psi} = \{A, B, C, D, E, se, sd, ar, tt, \alpha, E_0\}$ . The second part of the model is the observational equation for the BOLD signal  $\mathbf{y}$  which is assumed to be observed with some additive Gaussian noise<sup>3</sup>,  $\mathbf{y} = g(\mathbf{x}, \boldsymbol{\phi}) + \boldsymbol{\eta}$ , with  $\boldsymbol{\phi} = \{V_0, E_0, \varepsilon\}$  and  $\boldsymbol{\eta}$  is a random error vector distributed according to the Gaussian distribution  $\mathcal{N}(0, \sigma_\eta^2 \mathbf{I})$  assuming unstructured noise. Under additional distributional assumptions about the model parameters  $\boldsymbol{\theta} = \{\boldsymbol{\psi}, \boldsymbol{\phi}\}$  and noise variance  $\sigma_\eta^2$ , we can apply Bayesian inference. In [9], Gaussian priors are chosen for all parameters. As explained in [7] for  $\varepsilon$ , it is more natural to use log-normal priors for parameters that are positive. A simple way to account for positivity while remaining in a Gaussian setting is to change the model parameterization. We consider equivalently  $\tilde{\boldsymbol{\theta}} = \{\tilde{A}, \tilde{B}, \tilde{C}, \tilde{D}, \tilde{E}, \tilde{se}, \tilde{sd}, \tilde{ar}, \tilde{tt}, \tilde{\alpha}, \tilde{E}_0, \tilde{V}_0, \tilde{\varepsilon}\}$ , where  $\{\tilde{A}, \tilde{B}, \tilde{C}, \tilde{D}\} = \{A, B, C, D\}$  remain unchanged while the other parameters take the form  $\tilde{\theta} = \log(\theta/\mu_\theta)$

<sup>3</sup>In this context of BOLD data sampled at discrete time points, we represent both data and state variables as vectors of discrete samples, not as scalar continuous functions of time as in section II

where the specific  $\mu_\theta$  values may depend on the experiment (see section V). An exception is  $E_0$  for which we set  $E_0 = \arctan(\tilde{E}_0 + \tan(\pi(\mu_{E_0} - 0.5)))/\pi + 0.5$  in order to ensure  $E_0 \in [0, 1]$ . Gaussian priors can then be assumed for  $\tilde{\boldsymbol{\theta}}$  and the state and observational equations above lead to,  $\mathbf{y} = h(\tilde{\boldsymbol{\theta}}, \mathbf{u}) + \boldsymbol{\eta}$ , with  $\boldsymbol{\eta} \sim \mathcal{N}(0, \sigma_\eta^2 \mathbf{I})$ ,  $\tilde{\boldsymbol{\theta}} \sim \mathcal{N}(\tilde{\boldsymbol{\theta}}, \boldsymbol{\Sigma}_\theta)$  and  $\sigma_\eta^2 \sim p(\sigma_\eta^2)$ . In contrast with previous work [9], [7], we use a semi-conjugate prior for the unknown parameters  $(\tilde{\boldsymbol{\theta}}, \sigma_\eta^2)$  in which  $\tilde{\boldsymbol{\theta}} \sim \mathcal{N}(\tilde{\boldsymbol{\theta}}, \boldsymbol{\Sigma}_{\tilde{\boldsymbol{\theta}}})$  independently of  $\sigma_\eta^2$  and a noninformative prior is used for  $\sigma_\eta^2$ , i.e.  $p(\sigma_\eta^2) \propto (\sigma_\eta^2)^{-1}$  (see Section 3.4, page 80, in [24]). Bayesian inference is then based on the posterior distribution  $p(\tilde{\boldsymbol{\theta}}, \sigma_\eta^2 | \mathbf{y}) \propto p(\mathbf{y} | \tilde{\boldsymbol{\theta}}, \sigma_\eta^2) p(\tilde{\boldsymbol{\theta}}) p(\sigma_\eta^2)$  whose mode provides the maximum a posteriori (MAP) estimate:

$$\begin{aligned} (\tilde{\boldsymbol{\theta}}, \sigma_\eta^2)_{MAP} &\in \arg \max_{\tilde{\boldsymbol{\theta}}, \sigma_\eta^2} \{ \log p(\mathbf{y} | \tilde{\boldsymbol{\theta}}, \sigma_\eta^2) + \log p(\tilde{\boldsymbol{\theta}}) + \log p(\sigma_\eta^2) \} \\ &\in \arg \min_{\tilde{\boldsymbol{\theta}}, \sigma_\eta^2} \{ (N+2) \log \sigma_\eta^2 + \frac{\|\mathbf{y} - h(\tilde{\boldsymbol{\theta}}, \mathbf{u})\|^2}{\sigma_\eta^2} + \\ &\quad + (\tilde{\boldsymbol{\theta}} - \bar{\boldsymbol{\theta}})^T \boldsymbol{\Sigma}_{\tilde{\boldsymbol{\theta}}}^{-1} (\tilde{\boldsymbol{\theta}} - \bar{\boldsymbol{\theta}}) \}. \end{aligned} \quad (3)$$

where  $N$  is the  $\mathbf{y}$  signal length. Setting the gradient with respect to  $\sigma_\eta^2$  to zero yields  $(\sigma_\eta^2)_{MAP} = \frac{\|\mathbf{y} - h(\tilde{\boldsymbol{\theta}}_{MAP}, \mathbf{u})\|^2}{N+2}$ . Plugging  $(\sigma_\eta^2)_{MAP}$  into expression (3) leads to

$$\begin{aligned} \tilde{\boldsymbol{\theta}}_{MAP} &\in \arg \min_{\tilde{\boldsymbol{\theta}}} \{ (N+2) \log \|\mathbf{y} - h(\tilde{\boldsymbol{\theta}}, \mathbf{u})\|^2 + \\ &\quad + (\tilde{\boldsymbol{\theta}} - \bar{\boldsymbol{\theta}})^T \boldsymbol{\Sigma}_{\tilde{\boldsymbol{\theta}}}^{-1} (\tilde{\boldsymbol{\theta}} - \bar{\boldsymbol{\theta}}) \}. \end{aligned} \quad (4)$$

Expression (4) corresponds to the fitness function to be optimized by the stochastic approaches. In contrast to the conventional Laplace approximation and EM estimation algorithm, evolutionary computation (EC) does not require the linearization or approximation of  $h(\tilde{\boldsymbol{\theta}}, \mathbf{u})$ . It does not require an analytic form of the likelihood and  $h(\tilde{\boldsymbol{\theta}}, \mathbf{u})$  can typically be used as a numerical function. Another advantage of EC is its flexibility in particular as regards hard constraints often imposed for stability of the differential equations (1). The hyperparameters  $\tilde{\boldsymbol{\theta}}$  and  $\boldsymbol{\Sigma}_\theta$  are specified in section V. We adapted the values used in SPM corresponding to human physiology to anesthetized rats based on [8], [22], [23] as specified in Table I.  $\boldsymbol{\Sigma}_{\tilde{\boldsymbol{\theta}}}$  was chosen to result in a non-informative prior to reflect the variable nature of that parameter.

## IV. METHODS

### A. Differential Evolution

Evolutionary computation methods are population-based and derivative-free MH algorithms [25] that try to reproduce natural evolution processes to reach a target which is generally represented as a fitness function to optimize. In practice, they implement an iterative process in which solutions “evolve” over generations until they converge to an optimum, starting from an initial pool of randomly generated solutions and without relying on first or second order information. EC procedures are MH algorithms based on achieving a trade-off between intensification (exploitation of the best solutions, usually through selection operators and replacement strategies) and diversification (exploration of the search space thanks

TABLE I

DEFINITION AND PRIORS FOR EACH OF THE 15 PARAMETERS OPTIMIZED. THE PRIOR MEANS CORRESPOND TO THE PHYSICAL MODEL PARAMETERS AS USED IN EQ. 1 ( $\theta$ ), THE PRIOR COVARIANCE VALUES CORRESPOND TO THE TRANSFORMED VALUES AS OPTIMIZED BY EACH OPTIMIZER ( $\tilde{\theta}$ ). PRIOR MEANS FOR THE PHYSIOLOGICAL PARAMETERS ADAPTED TO ANESTHETIZED RATS WERE TAKEN FROM † SPM DEFAULTS, ‡ [8], AND \* [22], [23]

Parameter	Definition	Prior Mean ( $\mu_\theta$ )	Re-Parametrization Formula	Prior Covariance ( $\Sigma_{\tilde{\theta}}$ )
$A$	Intrinsic coupling from inhibitory to excitatory neuron populations within the region	0	$A = \tilde{A}$	0.25
$B$	Strength of the modulation of inhibitory to excitatory connections due to the input $u$	0	$B = \tilde{B}$	0.25
$C$	Gain of direct (exogenous) inputs to the system (e.g. sensory stimuli)	0	$C = \tilde{C}$	55
$D$	Constants controlling the gating of the connection between neuronal populations as a function of neuronal activity, the vasoactive signal and blood flow	[0, 0, 0]	$D = \tilde{D}$	0.0498 · [1, 1, 1]
$E$	Decay rate of neuronal activity	1	$E = \mu_E \cdot \exp(\tilde{E})$	0.0498
$se$	Spike exponent introduced for the present dataset to control the scaling of the synaptic activity with respect to the spike amplitude derived from local field potentials (LFPs)	1	$se = \mu_{se} \cdot \exp(\tilde{se})$	0.1353
$sd$	Vasodilatory signal decay rate	0.64†	$sd = \mu_{sd} \cdot \exp(\tilde{sd})$	0.1353
$ar$	Rate constant for autoregulatory feedback by blood flow	0.41‡	$ar = \mu_{ar} \cdot \exp(\tilde{ar})$	0.0498
$tt$	Transit time of blood from the arteriolar to the venous compartment	0.98‡	$tt = \mu_{tt} \cdot \exp(\tilde{tt})$	0.0498
$\alpha$	Grubb's vessel stiffness exponent	0.32†	$\alpha = \mu_\alpha \cdot \exp(\tilde{\alpha})$	0.0067
$V_0$	Resting venous cerebral blood volume fraction	0.04†	$V_0 = \mu_{V_0} \cdot \exp(\tilde{V}_0)$	0.0498
$E_0$	Oxygen extraction fraction at rest	0.55*	$E_0 = \arctan(\tilde{E}_0 + \tan(\pi(\mu_{E_0} - 0.5)))/\pi + 0.5$	0.0067
$\varepsilon$	Ratio of intra to extravascular BOLD signal	1	$\varepsilon = \mu_\varepsilon \cdot \exp(\tilde{\varepsilon})$	0.1353

to crossover and mutation operators). Some relevant mathematical proofs can be found in the literature about the MHs convergence properties [26], [27], [28].

In this work, we choose to use Differential Evolution (DE) [29], which has recently been shown to be one of the most successful EC methods for global continuous optimization and biomedical image analysis problems [30], [31]. DE perturbs individuals in the current generation by the scaled differences of other randomly selected and distinct individuals. In DE, each individual acts as a parent vector, and for each of them a new solution, called donor vector, is created. In the basic version of DE, the donor vector for the  $i^{th}$  parent ( $\tilde{\theta}_i$ ) is generated by combining three random and distinct elements  $\theta_{r1}$ ,  $\theta_{r2}$  and  $\theta_{r3}$ . The donor vector  $V_i$  is computed as  $V_i = \theta_{r1} + F \cdot (\tilde{\theta}_{r2} - \tilde{\theta}_{r3})$ , where  $F$  (scale factor) is a parameter that typically lies in the interval [0.4, 1]. The original method described above is called DE/rand/1, which means that the first element of the donor vector equation  $\theta_{r1}$  is randomly chosen and only one difference vector (in this case  $\tilde{\theta}_{r2} - \tilde{\theta}_{r3}$ ) is added. After mutation, every parent-donor pair generates a child (or trial vector) by means of a crossover operation. The crossover is applied with a certain probability, defined by a parameter  $Cr$  that, like  $F$ , is one DE control parameter. Then, the trial vector is evaluated and its fitness is compared to the parent's. The best, in terms of fitness, survives and will be part of the next generation.

### B. Differential Evolution Markov Chain

Differential Evolution Markov Chain (DEMC) [32] is a population Markov Chain Monte Carlo (MCMC) algorithm, in which multiple chains are run in parallel. In DEMC the jumps are a fixed multiple of the differences of two random vectors in the population. The scale and orientation of the jumps in DEMC automatically adapt themselves to the variance-covariance matrix of the target distribution. The main advantages of DEMC over conventional MCMC are simplicity, speed of calculation and convergence, even for nearly collinear parameters and multimodal densities. For every generation and member of the population, a candidate solution is created through DE mutation (strategy DE/rand/1), and the selection process, by which a candidate solution will substitute an old one, is guided by the Simulated Annealing (SA) cooling schedule temperature. In practical terms, DEMC includes a Metropolis step on DE with multiple chains, in which chains learn from each other. It could be considered as parallel adaptive direction sampling with the Gibbs sampling step replaced by a Metropolis step, or as a non-parametric form of Random-Walk Metropolis.

### C. Expectation-Maximization/Gauss-Newton

The SPM package provides a tool to perform the Bayesian inversion of a nonlinear model using the EM/GN algorithm

[9], [33]. The procedure conforms to an EM implementation of a GN search for the maximum of the conditional or posterior density. The E-Step uses a Fisher-Scoring scheme and a Laplace approximation to estimate the conditional expectation and covariance of the parameters. If the free-energy starts to increase, a Levenberg-Marquardt scheme is invoked. The M-Step estimates the precision components in terms of restricted maximum likelihood point estimators of the log-precisions. EM/GN stops the process if the improvement of the fitness function is less than  $10^{-4}$  between successive iterations for three iterations in a row. Traditionally, EM/GN is run from physiologically reasonable parameter values, i.e. the prior means, which facilitate its convergence to a global optimum. However, this algorithm is known to be sensitive to initialization and prone to get stuck in local optima. In this paper, we also use a stochastic version of EM/GN in which this local solver is run from multiple starting points.

#### D. Other methods

Other works [34] cite methods like binary Genetic Algorithm (GA), SA and particle filters to potentially solve a similar problem. Of the possible methods to compare to, the EM/GN approach included in SPM is still the most widely used and constitutes a benchmark for this application, and DE consistently outperformed other MHs such as binary GA and SA in many real-world optimization problems over the last 15 years [29]. Other techniques, like particle filters, rely on critical design choices (number of particles, prior) and their implementation is difficult for large number of parameters ([34] shows unsatisfying results with very large variances on real data estimating only 7 parameters).

### V. EXPERIMENTAL RESULTS

#### A. Datasets

1) *Real Dataset*: The BOLD data used were recorded to test biophysical models in the context of epileptic activity in rats. An intracortical silica capillary was surgically implanted in the right primary somatosensory cortex of male Wistar rats ( $\sim 400$  g) and two subdural carbon EEG electrodes were placed close to the injection site and one over the cerebellum. Epileptic activity was elicited using bicuculline methochloride (2.5 mM,  $1\mu\text{l}/5$  min) injected intra-cortically during the MRI session. Simultaneous EEG and BOLD-fMRI data were acquired under  $<2\%$  isoflurane anesthesia. All procedures were performed according to the French guidelines on the use of living animals in scientific investigations, with the approval of the institutional review board.

The EEG/fMRI data were acquired on a 4.7 T Advance III Bruker Biospec at the Grenoble MRI facility IRMaGe. In each scan, 300 volumes of five slices ( $0.25 \times 0.25 \times 0.8$  mm<sup>3</sup> voxel size) were acquired using single-shot GE EPI with TE/TR of 20/600 ms. A total of 3-12 scans were performed for each of 12 rats (27 min of EEG/fMRI data per animal on average). The data from 3 animals were unexploitable and thus excluded from the analysis. Epileptic discharges (EDs) were automatically identified from the EEG data and ED amplitudes and onsets were recorded. In order to obtain signals with

adequate SNR, a single average fMRI signal was extracted for each rat from the largest cluster of significantly active voxels identified in a linear analysis with a FIR hemodynamic response model within a manually defined region of interest around the bicuculline injection site. EEG and BOLD data from all scans were concatenated to form a single time series. The fMRI signal size  $N$  ranged from 894 to 3576 with a median value of 2684. The EDs were entered in the biophysical model via the input function  $u$  as a series of short (8 ms) events.

2) *Synthetic Dataset*: A synthetic dataset was created to study the methods behavior with data created under controlled conditions. The animal, whose physiological conditions were amongst the most stable ones (in this case, rat 9), was selected as a reference template to create this synthetic dataset, and the parameter estimates found by EM/GN initialized from the prior means were defined as the ground truth (GT). The epileptic spikes from rat 9 were subsampled and  $AR(1)$  autoregressive noise [35] was added. BOLD signals were generated from either a full set of measured spikes (100%) or a subset to simulate more sparse events (25%). In a first step, ten Signal-to-Noise ratios (SNRs) were tested: 10%, 17%, 28%, 46%, 77%, 129%, 215%, 359%, 599% and 1000%. EM/GN was used to estimate parameters from these data sets and the Euclidean distance to the GT was computed as a function of SNR. Based on the results obtained, we generated the final synthetic data in a second step using three representative SNRs: 215% (“good fit”), 46% (“intermediate fit”) and 10% (“bad fit”). These data were subsequently used to compare all three optimization methods.

#### B. Methods Configuration

For each dataset, physiological parameters  $\theta$  are estimated using the DE and DEMC approaches on  $\tilde{\theta}$  with the fitness function shown in Eq. (4) and transforming the resulting  $\tilde{\theta}$  back into  $\theta$ . At the end of every EM/GN iteration, Eq. (4) is used to obtain a fitness value directly comparable to the one of DE and DEMC. The prior means are then set to  $\bar{\theta} = \mathbf{0}$  and the prior covariance  $\Sigma_{\tilde{\theta}}$  is a diagonal matrix containing the prior variances as shown in Tab. I.

Since DE and DEMC are stochastic approaches, several runs need to be executed to evaluate the stability and average performance of each method. In this study, 20 runs are performed on each dataset and the maximum number of iterations per run is set to 300. The DE parameters used are among the most common ones in the state of the art [29] and the default ones used in the codes developed by the authors<sup>4</sup>:  $F = 0.85$ ,  $C_r = 1$ , with a DE/local-to-best/1/bin strategy that attempts a balance between robustness and fast convergence, and a population size of 150. DEMC uses the same population size and maximum number of iterations as DE to allow for an easy comparison between the two stochastic approaches. Also, in order to study its general behavior, EM/GN [9] was executed 100 times from random initializations (including the prior means). Finally, DEMC was also run using 1500 iterations in order to verify the improvement in performance associated

<sup>4</sup><http://www1.icsi.berkeley.edu/~storn/code.html#matl>

with a larger execution time. All methods are implemented in MATLAB and the total number of runs was 2700, corresponding to 1800 optimization runs with real data (12 rats, 100 repetitions of EM/GN, 20 repetitions of DE and DEMC, and 10 repetitions using DEMC with 1500 iterations) and 900 optimization runs with synthetic data (6 synthetic datasets, 100 repetitions of EM/GN, 20 repetitions of DE and DEMC, and 10 repetitions using DEMC with 1500 iterations). Each EM/GN iteration implies 21 integrations of the differential equations (the most time consuming task within the fitness function), while in DE and DEMC each iteration needs 150 integrations (45000 integration operations per run).

The main idea behind the convergence criteria in DE is that there is a minimum fitness value to reach ( $F_{VTR}$ , in this case 0), and the optimization algorithm will stop its minimization of function  $f$  if either the maximum number of iterations  $I_{itermax}$  (in this case 300) is reached, like in DEMC, or the best parameter vector  $FV_{best}$  has found a value  $f(FV_{best}) \leq F_{VTR}$ .

To trigger further research in the estimation of biophysical parameters using neuroscientific models, our synthetic datasets and the toolbox implementing the proposed approach will be made publicly available at MATLAB Central File Exchange.

### C. Synthetic Data Results

The three metrics used to evaluate performance were the BOLD fitting measure (to be maximized), the fitness value (to be minimized) and the distance to GT (to be minimized). The BOLD fitting measure, computed as  $(d_{ini} - d_{fin})/d_{ini}$  where  $d_{ini}$  is the variance of the raw data and  $d_{fin}$  is the variance of the residuals after fitting the model, represents the amount of variance in the original signal which is explained by the model: the value is 1 if the fitting is perfect and smaller than 0 if the final set of parameters found is fitting the actual signal worse than a zero BOLD signal. In turn, the fitness value corresponds to the value achieved by the optimization methods according to Eq. (4), and the GT distance for a particular parameter set  $\theta$  is determined by the root mean square of  $((\theta - \hat{\theta})/\theta)$ , where  $\theta$  is the GT and  $\hat{\theta}$  represents the estimated parameter set found respectively by each optimization algorithm. Importantly, to compute the GT distance only physiologically meaningful parameters (last seven parameters in Table I: from  $sd$  to  $\varepsilon$ ) are taken into account. Since EM/GN is very dependent on the initialization and may perform poorly if the initial configuration is far from a global optimum, we perform an outlier rejection procedure prior to calculating the average performance consisting simply on the removal of solutions which provide a negative or zero BOLD fitting value.

The mean number of EM/GN iterations to converge was  $37 \pm 18$  (max: 135, min: 11), so the average number of integrations to obtain the final result is 784. Table II contains the mean and standard deviation of the results obtained by each method and synthetic dataset. Column 4 indicates the number of results not taken into account to compute the statistics. We have also included a column with the solution found running EM/GN using the prior means as initial values. The last two columns show the results obtained by DEMC using 1500

iterations to verify the improvement achieved by increasing the execution time. Fig. 1 displays the distributions of the parameter estimates found for four physiologic parameters.

Among the methods under comparison, DE shows the most stable behavior, achieving a similar performance in different runs. This is confirmed both by the low standard deviation of the fit quality metrics as well as the reduced variability in parameter space. EM/GN on the other hand appears to be very dependent on the initialization and generally shows the highest spread in all metrics. Also, DE presents on average the best performance according to the three metrics under consideration. The improvement obtained by DEMC when running 1500 iterations (with respect to using 300 iterations) could justify the increase in computational time. Within each dataset, both the BOLD fitting measure as well as the fitness value are consistently correlated with the GT distance, providing evidence that these first two measures are good markers of the quality of the parameter estimates found.

Surprisingly, in Table II, for synthetic dataset 3, increasing the number of iterations up to 1500 in DEMC degrades the results in terms of mean GT distance and standard deviation. A plausible explanation for this phenomenon could be found in the exploratory nature of DEMC and the characteristics of the problem at hand. It seems like DEMC intensively explores the search space and it is able to find very diverse solutions which are better in terms of BOLD fitting and fitness value. But, those sets of parameters are progressively different from the GT. On the other hand, this possible explanation would go in the same direction that other research works [34], [36], where very different parameters could give nearly identical BOLD output; meaning that, without properly constraining the parameter values, some of them may not be precisely ascertainable. This could explain discrepancies of parameter estimates in previous studies.

Fig. 1 shows that, for all four parameters considered here, the average estimates tend to be generally closer to the GT than to the prior means. This indicates that these particular model parameters can be identified from BOLD data.

### D. Real Data Results

In EM/GN, the average number of iterations until convergence is  $31 \pm 18$  (max: 128, min: 8) with an average number of integrations of 646. The median estimates from DE, DEMC and EM/GN are shown in Table III. The experimental conditions for all animals were controlled as closely as possible. It is therefore expected that the physiologically meaningful parameters show limited variability across animals. However, the parameters related to the scaling of the stimulus (notably,  $B$ ,  $C$  and  $se$ ) may vary significantly, since the amplitudes of the elicited EEG responses varied between sessions. Even though the administration protocol was performed to be identical to the extent possible, the amount of the drug that actually ended up in the tissue likely varied between animals depending on factors such as the diffusion or leakage of the drug along the injection path. The injected drug, bicuculline methochloride, is an antagonist of GABA<sub>A</sub> receptors, and thus modulates the coupling from inhibitory to excitatory neurons,

TABLE II

DE, EM/GN AND DEMC OPTIMIZATION VALUES FOR EACH OF THE 6 SYNTHETIC DATASETS. THE DECIMALS HAVE BEEN REMOVED IN THE MEAN FITNESS VALUES TO FACILITATE VISUALIZATION AND COMPARISON BETWEEN METHODS. THE BEST RESULTS OBTAINED PER DATASET ARE DISPLAYED IN BOLD. THE LOWER THE FITNESS VALUE THE BETTER THE RESULT.

Fig. 1. Boxplots for parameters  $\alpha$ ,  $tt$ ,  $\epsilon$ ,  $V_0$  for synthetic dataset 2. The green horizontal line represents the GT and the diamond displays the estimate achieved using EM/GN from the prior means. Since the actual EM/GN spread is much larger in all cases, we have zoomed-in on a sub-interval to better visualize the differences between the methods. The prior means and prior covariances are displayed as horizontal solid and dashed black lines, respectively.

represented by the parameters  $A$ ,  $B$  and  $D$ . We observe significant variability in these parameters, both across animals and across optimization methods. Analysis of this variability is complicated by the fact that  $A$ ,  $B$  and  $D$  interact and variations in one of the parameters may be partially compensated by variations in another. Thus, the observed variability may also be due to identifiability issues. Estimates across animals for four of the parameters that are expected to be among the most stable, namely  $\epsilon$ ,  $\alpha$ ,  $tt$  and  $V_0$ , are shown in Fig. 2.

The estimates found by DEMC for  $B$  are less stable and remarkably lower than the ones found by EM/GN and DE. This behavior can possibly be explained using the same arguments used for synthetic dataset 3 in Table II (DEMC exploratory ability and identifiability issues), and also considering that the

values found for  $B$ , due to the complexity of the problem, can balance out with the values found for other parameters in a way that can equally result in a good fitness value.

Fig. 3 shows the median fitness evolution for two different cases (rats 1 and 10, respectively), and also highlights that DE and DEMC are able to continue exploring the search space, improving the solutions found, while EM/GN is prone to converge to a local optimum. According to this figure, a smaller number of DE iterations might have been sufficient to achieve a good result: the x-axis of Fig. 3 uses a logarithmic scale and, from iterations 150 to 300, the improvement achieved by DE is almost irrelevant compared to the doubling in computation time necessary for the extra 150 iterations.

The values estimated by DE are markedly more stable than

the values obtained with EM/GN and DEMC. Quantitatively, the median parameter estimates from all three methods are plausible. Blood transit times from arterioles to the deoxygenated vascular compartment estimated with all methods are closer to 0.7 s which is somewhat lower than the prior mean of 0.98 s but still physiologically plausible. Individual runs of EM/GN can lead to much lower or higher unphysiologic estimates, depending on the initial value used in the estimation (Fig. 4 and Tab. III). For comparison, mean transit times across the entire vascular tree in a cortical voxel observed using DSC MRI in anesthetized rats are on the order of 1.6 s (from [37]). Equally, estimated resting venous blood volumes are lower than the prior estimate of 4% taken from SPM defaults, which also corresponds to the total cortical resting blood volume in isoflurane anesthetized male Wistar rats [37]. In hindsight, the value that should actually be considered in the model is however only the venous (deoxygenated) fraction of that, such that a value of 2% actually seems much more realistic than the much higher values estimated in some of the runs using EM/GN and DEMC. Finally, all methods on average yield values for the intra- to extra-vascular BOLD signal ratio and Grubb exponent that are similar across methods. Estimates are close to the prior means for the Grubb exponent. Given the results obtained on synthetic data, this is an indication that the prior means are close to the unknown GT. In summary, the estimates obtained from DE for these values seem both more stable and more realistic or at least as realistic across sessions as the estimates from EM/GN and DEMC. Fig. 4 displays the boxplots per method and rat for  $V_0$  and  $tt$  where DE presents again a very low variability. It is important to highlight that EM/GN without at least several runs with different initial values produces unstable results (both in terms of the fitness function value, as witnessed by their large standard deviation, as well as in parameter values, as shown in the boxplots), but other methods, like DE, can solve this problem in a stable fashion, given prior information.

The fitness values achieved per method (mean and standard deviation) are shown in Table IV using the same criteria as explained in Section V-C. DE again is the best method in terms of BOLD fitting and fitness value. It is important to emphasize the different nature of the algorithms under study: EM/GN works with only one solution in a deterministic fashion, while DE and DEMC deal with a population of candidate solutions with a stochastic strategy. Commonly, DE and DEMC (especially when using 1500 iterations) have a more stable behavior as reflected in a lower standard deviation. These results can have a decisive impact within the neuroscientific community since, from the practical point of view, neuroscientists usually select one single starting solution and run EM/GN from there, obtaining sometimes reasonable results but, also quite commonly, clearly improvable ones (in Table IV, the results obtained by DE outperformed in all cases the ones obtained by EM/GN from the prior means, i.e. our best estimate of parameter values based on existing literature).

Statistical tests were performed to study the statistical significance of the results obtained in terms of BOLD fitting and fitness value (see Table V): the mean ranks represent the average position of each method per rat, while the p-value

is computed using a non-parametric statistical test (since the normality and homoscedasticity assumptions are not met, as usual with EC methods [38]) between the first method and the other two. As shown in Table V, DE and DEMC, in real data, are on average the first and the second best methods according to both fitness function value and BOLD fitting.

## VI. CONCLUSION AND FUTURE WORK

Two stochastic methods (DE and DEMC) have been applied to estimate biophysical parameters in fMRI data and they have proven to be able to obtain physiologically feasible results. In particular, DE shows the robustness and flexibility of global search optimization methods while being able to incorporate prior information in a principled Bayesian way. DEMC can also provide consistent solutions but with a much larger number of iterations. Preliminary results on real and synthetic data show that DE is able to achieve sensible parameter estimates with a more stable and consistent behavior, improving in terms of fitness value and fMRI signal fitting in real data, than the traditional and widely used EM/GN approach (*de facto* standard in the SPM package). Traditionally in cognitive neuroscience EM/GN is run from the prior means to obtain the estimates, but the large spread in parameter values and its lack of reliability in terms of fitness values provide evidence to justify the use of stochastic approaches (either EM/GN from different random initial solutions or a MH-based approach). The formulation presented here is generic and can be adapted to other forward generative models that relate neuronal and physiological variables to macroscopic data (e.g. [39], [40], [41]), mainly by modifying functions  $g$  and  $h$  (Section III).

Before issuing a definitive conclusion, DE should be compared with alternative approaches like single-chain adaptive MCMC [42], Hamiltonian MCMC [43], Belief Propagation [44] or Langevin diffusion [45]. Also, as future work, we could take advantage of the inherent property of EC methods to provide a set of solutions instead of a single one, giving information about the range of values for each parameter that are consistent with the data. Testing on multimodal fMRI data may also help to further improve the reliability of the parameter estimates, since cerebral blood flow and volume dynamics can provide additional information.

## ACKNOWLEDGMENT

The authors thank J.-F. Scariot and T. Perret for their extremely valuable help regarding the technical tools used. Grenoble MRI facility IRMaGe was partly funded by the French program “Investissement d’Avenir” run by the “Agence Nationale pour la Recherche”; grant “Infrastructure d’Avenir en Biologie Santé” - ANR-11-INBS-0006.

Fig. 2. Boxplots of the EM/GN, DE and DEMC results for  $\varepsilon$ ,  $\alpha$ , transit time ( $tt$ ), and  $V_0$  using globally all real datasets. The parameters prior mean and standard deviation are indicated by the horizontal black lines (solid and dashed, respectively). Since the EM/GN variability is much larger in all cases, we have zoomed-in on a sub-interval for a better visualization.

TABLE IV  
OPTIMIZATION VALUES FOR EACH OF THE 12 RATS. THE DECIMALS HAVE BEEN REMOVED IN THE MEAN FITNESS VALUES. THE BEST RESULTS OBTAINED PER RAT ARE DISPLAYED IN BOLD. THE LOWER THE FITNESS VALUE THE BETTER THE RESULT.

**Pablo Mesejo** received the M.Sc. and Ph.D. degrees in computer science from Universidad da Coruña (Spain) and Università degli Studi di Parma (Italy), respectively. He performed his Ph.D. as Early Stage Researcher within the Marie Curie ITN MIBISOC (“Medical Imaging using Bio-Inspired and Soft Computing”). After that, he was working as post-doctoral researcher at the ALCov team (Advanced Laparoscopy and Computer Vision) of Université d’Auvergne (France). Currently he works as post-doctoral researcher for INRIA Grenoble Rhône-

Alpes (France). His research interests include computer vision and bio-inspired/soft computing methods, as well as their application to real-world problems in biomedical image/signal processing and analysis.

**Jan M. Warnking** received masters degrees in physics from the State University of New York at Stony Brook, US, and from the Julius Maximilians Universität Würzburg, Germany, and a PhD in physics from the Université Joseph Fourier in Grenoble, France. Since 2007 he holds a tenure position at the Institut National pour la Santé et la Recherche Médicale (Inserm) working at the Grenoble Institute of Neuroscience. His expertise is in MR physics and his research activities cover work on human and small animal fMRI data acquisition and biophysical

models, cerebral blood flow and vasoreactivity measurements, as well as MR safety of implants.

**Sandrine Sallet** graduated in Biologie Intégrative et Physiologie from Université Pierre et Marie Curie, Paris, France, in 2006 and PhD degree in Neuroscience from Université Joseph Fourier, Grenoble, France, in 2010. After that, she was working as post-doctoral researcher at Institut de Neurosciences des Systèmes, Marseille, France and at Grenoble Institut des Neurosciences, Grenoble, France, respectively. Since 2014, she works as postdoctoral researcher at the Gladstone Institutes, San Francisco, United States of America. Her expertise is in electrophysiology and her main research area is currently focused on understanding the neuronal processes underlying cognitive decline in Alzheimer’s disease.

ology and her main research area is currently focused on understanding the neuronal processes underlying cognitive decline in Alzheimer’s disease.

**Olivier David** graduated in applied physics from Ecole Normale Supérieure in 1999 and is an expert of functional neuroimaging, electrophysiology and neural modeling. In 2005, he obtained a tenure position to coordinate an EEG/fMRI program in humans and rodents at the Inserm U836 Grenoble Institute of Neuroscience, France. The main focus of his current research is to understand the effects of brain electrical stimulation on the organisation of functional networks using fMRI, intracerebral EEG and neural modeling.

**Florence Forbes** received the B.Sc. and M.Sc. degrees in computer science and applied mathematics from the Ecole Nationale Supérieure d’Informatique et Mathématiques Appliquées de Grenoble (EN-SIMAG), France, and the PhD degree in applied probabilities from the University Joseph Fourier, Grenoble, France. Since 1998, she has been a research scientist with the Institut National de Recherche en Informatique et Automatique (INRIA), Grenoble Rhône-Alpes, Montbonnot, France, where she founded the MISTIS team and has been the team

head since 2003. Her research activities include Bayesian analysis, Markov and graphical models, and hidden structure models.

**Christian Bénar** (SM’99, M’15) was born in Dijon (France) in 1971. He received the engineering degree from Ecole Supélec (Metz and Paris, France) in 1994, and the PhD degree in biomedical engineering from McGill University (Montréal, Canada) in 2004. He worked for Stellate Systems (Montréal) on software for EEG analysis between 1995 and 1997. Since 2006 he is a researcher at INSERM in Marseille (France). In 2012 he became head of the Dynamical Brain Mapping team at Institut de Neurosciences des Systèmes (INS), a joint INSERM-

Aix-Marseille University laboratory. Since 2015 he is the scientific head of the Magnetoencephalography (MEG) platform of the INS, hosted in the clinical neurophysiology department of the Timone hospital from AP-HM in Marseille. His main area of research is multimodal signal processing for brain mapping, in particular EEG, MEG and intracerebral EEG, with application to cognition and epilepsy.
